## 1 Satellite galaxies around a massive central

We once again have the number density profile for satellite galaxies around a massive central (dark matter) halo. The spherical volume element $dV$ can be defined as follows: We know that the volume can be computed in spherical coordinates using the triple integral

$$\iiint_V n(x)dV = \int_{\phi=0}^{2\pi}\int_{\theta=0}^{\pi}\int_{x=0}^{x_{max}} n(x)x^2 \sin\theta\, dx\, d\theta\, d\phi \tag{1}$$

$$= \int_{x=0}^{x_{max}} 4\pi n(x)x^2 dx = \int_{x=0}^{x_{max}} N(x)dx \tag{2}$$

$$= 4\pi A\langle N_{sat}\rangle \int_{x=0}^{x_{max}=5} x^2 \left(\frac{x}{b}\right)^{a-3} \exp(-\left(\frac{x}{b}\right)^c)dx = \langle N_{sat}\rangle \tag{3}$$

$$= 4\pi A\langle N_{sat}\rangle \int_{x=0}^{x_{max}=5} x^{a-1} \left(\frac{1}{b}\right)^{a-3} \exp(-\left(\frac{x}{b}\right)^c)dx = \langle N_{sat}\rangle \tag{4}$$

$$-> A = \frac{1}{4\pi \int_{x=0}^{x_{max}=5} x^{a-1} \left(\frac{1}{b}\right)^{a-3} \exp(-\left(\frac{x}{b}\right)^c)dx} \tag{5}$$

Where we have defined the number of satellites N(x)dx in the infinitesimal range [x, x+dx). Since n(x) where x is the radius relative to virial radius $x = r/r_{vir}$ is only dependent on x, we can easily solve for $\theta$ and $\phi$. Dividing by $\langle N_{sat}\rangle$ on both sides and rearranging gives us an expression for $A$.

The general calling code for all subquestions is included below. Specific functions used for one or several subquestions are shown at that subquestion.

```python
# imports
from collections.abc import Callable
from functools import partial
import matplotlib.pyplot as plt
import numpy as np

## 1.1 (1a) Maximum of N(x)

For this question we are asked to find the maximum of N(x), the number of satellites in the infinitesimal range [x, x+dx), for given values of a, b, c, $N_{sat}$ and $A$. Let us first examine both functions.

Figure 1: n(x) dx, the number density profile, compared to N(x) dx, the number of satellites in the infinitesimal range [x, x+dx)

Although n(x), the number density profile, is a monotonically decreasing function, because the number density will decrease with radius, N(x) has a maximum because it can first increase at small x while the $x^2$ term gets larger, before the exponential decay dominates at larger radii.

Since this is a one-dimensional minimization problem, we employ a Golden Section Search minimizer together with the unnamed algorithm for bracketing a minimum to find the maximum of N(x). We first define a partial function $N_{1a}$(x) with a, b, c, $N_{sat}$ and $A$ filled in. We then define a function $N_{1a,neg}$ = -$N_{1a}$(x), the negative of the above function. The reason for this is that a minimization algorithm applied to the negative of a function f(x) can find the x coordinate where f(x) is at a maximum. Filling in that x-value in $N_{1a}$(x) gives us the maximum value of the function.

The unnamed bracketing algorithm starts with two x-value points a and b (not to be confused with the a and b constants of n(x)). It then proposes new points until it is certain that the three point bracket a,b,c contains a minimum. To show this algorithm is successful in bracketing a minimum, we start it with a=1, b=1.1, even though we can see from the plot the minimum is around x=0.2. The three point bracket then becomes (-0.5326237921249277, 0.15278640450004133, 0.5763932022500207). Note that the first point is outside the provided x range (0,5). In this case this is not a problem as there are no additional local minima and the function is defined outside the range (0,5), but it is something to always keep in mind when applying this algorithm.

The Golden Section Search minimizer divides this three point bracket into smaller and smaller intervals, ensuring the interval to be self-similar. This means that if we start with two intervals A (between point a and b) and B (between point b and c), we pick a new point d in such a way that A/B = B/C = $\phi$, the golden ratio. Here C is the interval between a and d. For each step we test in which interval the minimum is now contained and adjust the outer edges of our bracket accordingly. This approach ensures best worst-case behaviour.

The maximum of $N(x)$ is found at:

$$x_{\max} \approx 0.229983$$

$$N(x_{\max}) \approx 267.845533$$

### 1.1.1 Code for N(x) maximization

```python
import math
from collections.abc import Callable

import numpy as np

def bracket_minimum(func: Callable, a: float, b: float) -> tuple[float, float, float]:
    """Use the algorithm on lecture 7 slide to find a a 3 point bracket for a function.
    Note that depending on the function and initial guess for a and b, this function is not guaranteed to find a bracket for only 1 minimum!
    There is no way to know this without evaluating the function at many points. This is why we have to restart often.
    """
    phi = (1 + math.sqrt(5)) / 2  # Golden ratio
    fa, fb = func(a), func(b)
    switched_ab = False
    if fb > fa:  # Step 1: ensure f(b) < f(a)
        fa, fb = fb, fa
        a, b = b, a
        switched_ab = True
    c = b + (b - a) * phi  # Step 2
    while True:
        if (fc := func(c)) > fb:  # Step 3a
            return (c, b, a) if switched_ab else (a, b, c)

        # Step 3b: fit a polynomial. for this we can use LU Decomposition of a Vandermonde matrix
        # OR (since the minimum of the polynomial can be analytically defined using a,b,c and fa,fb,fc), we use the formula for this on slide 11 (Brent's method)
        d = b - 0.5 * (b - a) ** 2 * (fb - fc) - (b - c) ** 2 * (fb - fa) / ((b - a) * (fb - fc) - (b - c) * (fb - fa))
        fd = func(d)
        if b < d < c:
            if fd < fc:  # Step 4
                return (b, d, c)
            if fd > fb:
                return (a, b, d)
            d = c + (c - b) * phi
        else:  # Step 5
            d = c + (c - b) * phi
        a, b, c = b, c, d
        fa, fb = fb, fc
```

```python

def golden_section_search(func: Callable, a: float, b: float, c: float, rel_target_acc: float = (np.finfo(float).eps) ** 0.5, max_num_iterations: int = 50) -> tuple[None | float, int]:
    """Iteratively tighten a 3 point bracket surrounding a minimum. This function assumes there is only 1 minimum inside the bracket.
    Use the algorithm defined in lecture 7 slide 10.
    For a minimization algorithm we can only hope to get as close to the minimum as the square root of the
    RELATIVE machine error epsilon times the x-value of the minimum, hence rel_target_acc: float = (np.finfo(float).eps) ** 0.5

    """
    phi = (1 + math.sqrt(5)) / 2  # Golden ratio
    w = 2 - phi
    c_min_b, b_min_a = abs(c - b), abs(b - a)
    other_edge = c if c_min_b > b_min_a else a  # Step 1

                c_min_b, b_min_a = abs(c - b), abs(b - a)  # I need more lines for the various cases,
                other_edge = c if c_min_b > b_min_a else a  # but it is more efficient because I do not always have to recompute both intervals and check which value should become other_edge
            else:
                c, b = b, d
                c_min_b, b_min_a = abs(c - b), abs(b - a)
                other_edge = c if c_min_b > b_min_a else a
        else:  # Step 4
            if b < d < c:
                c = d
                c_min_b = abs(c - b)  # Step 5 optimization: only recompute tightened interval. Here larger interval is b_min_a
                other_edge = a
            else:
                a = d
                b_min_a = abs(b - a)
                other_edge = c
        iteration += 1
    return None, iteration
```

## 1.2 (1b) $\chi^2$-fit

For each halo-mass bin, we want to fit the same parametric profile N(x;a,b,c) separately. This yields five different best-fit parameter sets (a,b,c), one for each mass bin. The normalization A is not an independent fit parameter, but is recalculated from a,b,c for each model using Romberg integration. Because the radial coordinate is normalized by the virial radius, the model describes the dimensionless shape of the satellite distribution, allowing that shape to vary with halo mass.

We are first asked to choose any number of radial bins, real or log space and x range. Since it is not clear from the question if this should vary per file, we assume our choices should be constant over all files (also because these choices are not variables in the template code for this question).

After reading in all files, we calculate the smallest and largest radius of all the satellite galaxies per halo. It turns out that there are no satellite galaxies with an x coordinate smaller than 1e-4, so we choose this as our $x_{min}$ value. The maximum x coordinate is around 2.5, so we simply keep $x_{max} = 5$ as our $x_{max}$ value. We choose logarithmically spaced bins in x to ensure sufficient resolution in the inner regions, where the satellite density varies rapidly, while still sampling the outer regions efficiently. We use 30 bins to balance resolution against Poisson noise, ensuring each bin contains a sufficient number of satellites.

We choose Levenberg-Marquardt as our minimization routine for the fitting procedure, because we are dealing with a model nonlinear in its parameters, we are proud of our LM class implementation and want to try a derivative based method for bonus points.

Since we are fitting our model to binned data, we are comparing the observed mean number of satellites per halo in radial bin i $N_i$, to the model prediction $\tilde{N}_i$ for the mean number of satellites per halo in radial bin i.

Our model is thus

$$\tilde{N}_i = 4\pi\langle N_{sat}\rangle A(a,b,c) I_i(a,b,c) \tag{6}$$

where we define

$$I_i(a,b,c) = \int_{x=i}^{x_{i+1}} x^2 \left(\frac{x}{b}\right)^{a-3} \exp(-\left(\frac{x}{b}\right)^c) dx = \int_{x=i}^{x_{i+1}} f(x) x^2 dx \tag{7}$$

and

$$I_{total} = \int_{x=0}^{x_{max}} f(x) x^2 dx \tag{8}$$

Note that A is dependent on a, b and c. The partial derivative of $\tilde{N}_i$ to each parameter is thus obtained using the product rule

$$\frac{\partial \tilde{N}_i}{\partial p} = 4\pi\langle N_{sat}\rangle \left(\frac{\partial A(a,b,c)}{\partial p} I_i(a,b,c) + A(a,b,c)\frac{\partial I_i(a,b,c)}{\partial p}\right) \tag{9}$$

Calculating the partial derivatives of f(x) with respect to a, b and c gives

$$\frac{\partial f(x)}{\partial a} = f(x) ln\left(\frac{x}{b}\right) \tag{10}$$

$$\frac{\partial f(x)}{\partial b} = f(x)\left(-\frac{a-3}{b} + \frac{c}{b}\left(\frac{x}{b}\right)^c\right) \tag{11}$$

$$\frac{\partial f(x)}{\partial c} = -f(x)\left(\frac{x}{b}\right)^c ln\left(\frac{x}{b}\right) \tag{12}$$

This gives for all p

$$\frac{\partial I_i}{\partial p} = \int_{x_i}^{x_{i+1}} \frac{\partial f(x)}{\partial p} x^2 dx \tag{13}$$

And using $A = (4\pi I_{total})^{-1}$

$$\frac{\partial A}{\partial p} = -4\pi A^2 \frac{\partial I_{total}}{\partial p} \tag{14}$$

So

$$\frac{\partial \tilde{N}_i}{\partial p} = 4\pi \langle N_{sat} \rangle A \left( \frac{\partial I_i}{\partial p} - \frac{I_i}{I_{total}} \frac{\partial I_{total}}{\partial p} \right) \tag{15}$$

Argue the choices of your binning. Explain the minimization routine used. Bonus points for a correctly implemented derivative-based routine.

Table 1: Best-fit parameters for $\chi^2$ fits.

| Dataset | $N_{\text{sat}}$ | $\chi^2$ | $a$ | $b$ | $c$ |
|---|---|---|---|---|---|
| m11 | 0.00000 | 0.00000 | 0.00000 | 0.00000 | 0.00000 |
| m12 | 0.00000 | 0.00000 | 0.00000 | 0.00000 | 0.00000 |
| m13 | 0.00000 | 0.00000 | 0.00000 | 0.00000 | 0.00000 |
| m14 | 0.00000 | 0.00000 | 0.00000 | 0.00000 | 0.00000 |
| m15 | 0.00000 | 0.00000 | 0.00000 | 0.00000 | 0.00000 |

    Parameters
    ----------
```

```
    model : callable
        The model function to compare to the data.
    data : ndarray
        The observed data to compare the model to.
    params : tuple
        The parameters to evaluate the model at.

    Returns
    -------
    float
        The chi-squared value for the given parameters and data.
    """
    # TODO: implement calculation of the chi2 value (or equivalent) using the model mean and variance to be minimized.

    return 0.0  # replace by the correct value
```

### 1.3 (1c) Poisson ln-likelihood fit

Explain how you determine the Poisson ln-likelihood. Describe the optimization method used. How do your best fit parameters differ from the ones obtained in (1b)? Why?

Table 2: Best-fit parameters for $\chi^2$ fits.

| Dataset | llh | $a$ | $b$ | $c$ |
|---|---|---|---|---|
| m11 | 0.00000 | 0.00000 | 0.00000 | 0.00000 |
| m12 | 0.00000 | 0.00000 | 0.00000 | 0.00000 |
| m13 | 0.00000 | 0.00000 | 0.00000 | 0.00000 |
| m14 | 0.00000 | 0.00000 | 0.00000 | 0.00000 |
| m15 | 0.00000 | 0.00000 | 0.00000 | 0.00000 |

Figure 3: Fit of the satellite number density profile using the Poisson log-likelihood method.

### 1.3.1 Code for Poisson ln-likelihood fit

NOTE: all code is reproduced below as an example, show only the relevant lines for this exercise here instead.

```
import numpy as np

def negative_poisson_ln_likelihood(model: callable, data: np.ndarray, params:
    tuple) -> float:
    """
    Calculate the Poisson negative log-likelihood for a given set of parameters
    and data.

```

```
    Parameters
    ----------
    model : callable
        The model function to compare to the data.
    data : ndarray
        The observed data to compare the model to.
    params : tuple
        The parameters to evaluate the model at.

    Returns
    -------
    float
        The Poisson negative log-likelihood value for the given parameters and data.
    """
    # TODO: implement calculation of the Poisson negative log-likelihood (or equivalent) to be minimized

    return 0.0  # replace by the correct value
```

## 1.4 (1d) Statistical tests

Table 3: Statistical tests for the $\chi^2$ and Poisson ln-likelihood fits.

| Method | Dataset | G | Q |
|---|---|---|---|
| $\chi^2$ | m11 | 0.00000 | 0.00000 |
| $\chi^2$ | m12 | 0.00000 | 0.00000 |
| $\chi^2$ | m13 | 0.00000 | 0.00000 |
| $\chi^2$ | m14 | 0.00000 | 0.00000 |
| $\chi^2$ | m15 | 0.00000 | 0.00000 |
| Poisson | m11 | 0.00000 | 0.00000 |
| Poisson | m12 | 0.00000 | 0.00000 |
| Poisson | m13 | 0.00000 | 0.00000 |
| Poisson | m14 | 0.00000 | 0.00000 |
| Poisson | m15 | 0.00000 | 0.00000 |

What can you conclude from the results of the statistical tests?
